**ABSTRACT**

Summary: The chemical structures of biomolecules, whether naturally occurring or synthetic, are comprised of functionally important building blocks. Given a set of small molecules—for example, those known to bind a particular protein—computationally decomposing them into chemically meaningful fragments can help elucidate their functional properties, and may be useful for designing novel compounds with similar properties. Here we introduce *molBLOCKS*, a suite of programs for breaking down sets of small molecules into fragments according to a pre-defined set of chemical rules, clustering the resulting fragments, and uncovering statistically enriched fragments. Among other applications, our software should be a great aid in large-scale chemical analysis of ligands binding specific targets of interest.

Availability: *molBLOCKS* is available as GPL C++ source code at http://compbio.cs.princeton.edu/molblocks.

**1 INTRODUCTION**

Endogenous small molecules are synthesized in the cell in a modular fashion, using building blocks or fragments that are often conserved across organisms (Muto *et al.*, 2007). Fragment-based drug discovery has also emerged as an important paradigm to navigate the diversity of the chemical landscape and to profile protein druggability (Hajduk and Greer, 2007). Further, it has been shown that the toxicity of certain drugs can be explained by the presence in their structure of fragments that are shared by toxic compounds (Ahmed *et al.*, 2011). While many programs are available to assemble small molecules from fragments (Schneider and Baringhaus, 2013), the reverse problem of breaking down small molecules and analyzing the corresponding fragment sets has been studied less extensively. An implementation of the the RECAP algorithm (Lewell *et al.*, 1998) to fragment small molecules can be found in a commercial program (*fragments*, www.chemaxon.com), and is available in the RDKit library (http://www.rdkit.org), which also implements the BRICS fragmentation algorithm (Degen *et al.*, 2008). However, given a diverse set of small molecules that share a property of interest, there is no automated tool to identify statistically enriched fragments that might explain their activity.

Here we introduce the *molBLOCKS* suite, which allows users to break down small molecules into chemically meaningful fragments and analyze the resulting fragment distribution (Figure 1). The software consists of two command-line programs: *fragment* and *analyze*. The *fragment* program reads user-defined rules to specify the bonds to break, or uses default sets of rules (RECAP (Lewell *et al.*, 1998), CCQ [www.chemaxon.com], and BRICS (Degen *et al.*, 2008)). Then, the program applies these rules to fragment the molecules, and generates all fragments with a number of heavy atoms above a minimum size defined by the user. The *analyze* program collects statistics on the frequency with which each fragment occurs, clusters fragments using a user-defined similarity threshold based upon a fingerprint representation (O’Boyle *et al.*, 2011) of the fragments, and selects a representative fragment for each cluster. This program can also perform enrichment analysis at the level of either fragments or clusters.

A typical scenario where fragment and enrichment analyses can be applied is when dealing with a library of small molecules, a subset of which have a specific property of interest. In these cases, *molBLOCKS* can be used to fragment the whole library, and determine which (if any) fragments are significantly enriched in...
53s on an iMac with a 2.66 GHz processor. A User’s Guide with 2006) collection of 6460 small molecules with the default rules took which these compounds derive. Molecules are visualized with base. The enriched fragment comes from nitrosurea, the molecule from which these compounds derive. Molecules are visualized with Marvin Sketch (http://www.chemaxon.com/products/marvin/marvinsketch/). The remaining enriched clusters are given in the Supplement.

the set with the property of interest. Fragmentation and enrichment analysis of small molecules may also be useful in analyzing proteins. For example, ligands bound by proteins that share a common property, such as a specific function, can be analyzed in this manner. Such an approach would provide a complement to the functional enrichment analyses that are routinely performed with Gene Ontology terms (Huang da et al., 2009).

Extensive fragmentation of the entire DrugBank (Wishart et al., 2006) collection of 6460 small molecules with the default rules took 53s on an iMac with a 2.66 GHz processor. A User’s Guide with implementation details and more tests is provided with the suite.

2 METHODS

2.1 fragment
Small molecules and bond-breaking rules are specified with SMILES (Weininger, 1988) and SMARTS (Daylight Inc.) notation, respectively. The open-source Open Babel C++ API (O’Boyle et al., 2011) is used to process the SMILES and SMARTS notation. To ensure that all possible fragments of a minimum given size are generated (extensive fragmentation, which can be turned on with the -e flag), the program uses the following strategy. Cleaveable bonds are represented as nodes in an undirected graph, with an edge between two nodes if both bonds can be cut; we note that not all bonds that match the rules can be cleaved at the same time, because doing so would yield fragments smaller than the minimum size. Subsequently, the Bron-Kerbosch algorithm (Bron and Kerbosch, 1973) is used to identify all maximal cliques (i.e., all sets of bonds that can be cleaved simultaneously). Finally, all possible fragments are generated by cutting the bonds within each maximal clique, one clique at a time. Without extensive fragmentation, the program returns only one possible set of fragments.

2.2 analyze

2.2.1 Fragment frequency The program returns a frequency distribution with the total number of molecules that contain a given fragment. Multiple instances of the same fragment in a molecule are counted only once.

2.2.2 Fragment clustering Fragments are first converted to the Open Babel (O’Boyle et al., 2011) default FP2 fingerprint representation, which is based upon linear segments of up to 7 atoms in length. The widely-used Tanimoto coefficient between the fingerprint representations of two fragments is employed to compute their fragment similarity. For a given threshold of similarity, a graph is created where there is a node for each fragment, and an edge between two nodes whose corresponding fragments are considered similar. Subsequently, the analyze program extracts the connected components of the graph, and selects a representative element for each cluster as the fragment with the highest average similarity to all the other fragments in the cluster.

2.2.3 Enrichment analysis Enrichment analysis can be carried out in order to identify whether specific fragments (or clusters of fragments) appear in a set of molecules more frequently than expected by chance, as compared to a background set of fragments. The hypergeometric distribution was chosen to model the probability of obtaining a number of fragments (or clusters of fragments) equal to or greater than the observed by chance alone, in analogy to what is routinely done in Gene Ontology enrichment analyses (Rivals et al., 2007). The analyze program returns both uncorrected p-values and FDRs obtained with the Benjamini-Hochberg procedure (Benjamini and Hochberg, 1995) to handle multiple hypothesis testing.

3 USAGE

As an example of how to use the molBLOCKS suite, we fragmented a set of antineoplastic drugs extracted from KEGG (Kanehisa et al., 2012) with the following command:

```
fragment -i antineoplastic.smi -r RECAP.txt -n 4 -o antineoplastic.frag -e
```

where antineoplastic.smi is a text file containing the small molecules in SMILES format to fragment. The RECAP.txt file contains a definition of the cleavable bonds, encoded as SMARTS patterns. The -e flag specifies extensive fragmentation, and the -n parameter controls the minimum size of a fragment, defined as the total number of heavy atoms. The antineoplastic.frag file contains the output of the fragmentation.

Subsequently, we identified the enriched fragments in a background dataset of drugs in KEGG with the analyze program:

```
analyze -i antineoplastic.frag -c 0.8 -e background.frag -o distr.txt
```

With the optional -c parameter, analyze clusters the fragments at the specified Tanimoto coefficient. The optional -e parameter specifies the background set for enrichment analysis; note that this set must contain the fragments in the input set in order for the results to be meaningful. Figure 2 shows an example of an enriched fragment and its parent molecules in the antineoplastic set. See the Supplement for further details.
