ABSTRACT

Motivation: Over the recent years, the field of whole metagenome shotgun sequencing has witnessed significant growth due to the high-throughput sequencing technologies that allow sequencing genomic samples cheaper, faster, and with better coverage than before. This technical advancement has initiated the trend of sequencing multiple samples in different conditions or environments to explore the similarities and dissimilarities of the microbial communities. Examples include the human microbiome project and various studies of the human intestinal tract. With the availability of ever larger databases of such measurements, finding samples similar to a given query sample is becoming a central operation.

Results: In this paper, we develop a content-based exploration and retrieval method for whole metagenome sequencing samples. We apply a distributed string mining framework to efficiently extract all informative sequence k-mers from a pool of metagenomic samples and use them to measure the dissimilarity between two samples. We evaluate the performance of the proposed approach on two human gut metagenome data sets as well as human microbiome project metagenomic samples. We observe significant enrichment for diseased gut samples in results of queries with another diseased sample and very high accuracy in discriminating between different body sites even though the method is unsupervised.

Availability: A software implementation of the DSM framework is available at https://github.com/HIITMetagenomics/dsm-framework

1 INTRODUCTION

Metagenomics is the study of microbial communities in their natural habitat using genomics techniques (Tyson et al., 2004). It is undergoing a boom due to proliferation of high-throughput sequencing technologies. Many studies focus at targeted sequencing of specific marker genes such as the 16S rRNA gene in bacteria, but recently there has been a growing interest in whole metagenome sequencing (see, e.g. Qin et al., 2010; The Human Microbiome Project Consortium, 2012). While targeted studies provide data for phylogenetic profiling at a lower cost, whole metagenomes provide much more information, for example, about the collective metabolism (Greenblum et al., 2012), and the population genetics of the community (Schloissnig et al., 2013). Recent studies have also found associations between features of whole human gut metagenomes and type II diabetes (Qin et al., 2012). New data are accumulating rapidly, with a popular web-based MG-RAST server (Meyer et al., 2008) listing almost 3000 public whole metagenomes.

Analysing whole-metagenome shotgun (WMS) sequencing data is very challenging. The original sample typically contains genetic material from hundreds to thousands of bacterial species of different abundances (Li et al., 2012), most of which have not been fully sequenced previously. After sequencing, we obtain a huge collection of short sequence reads whose species of origin is unknown. While significant progress has been made, analysis relying on either the limited previously annotated genomes, or assembling the reads into novel more complete genomes, remains difficult and inefficient, and potentially susceptible to annotation biases.

In this paper we introduce an efficient purely data-driven feature extraction and selection method as well as similarity measures for WMS sequencing data sets, and apply them in retrieval of similar data sets. Such content-based retrieval is an extremely powerful tool for exploration of the data and generating hypotheses of disease associations, as previously demonstrated with gene expression data (Caldas et al., 2009, 2012). Retrieval from existing databases makes it possible to automatically explore a much greater variety of hypotheses than relying solely on the more common specifically designed focused studies.

Content-based similarity measures and retrieval of similar metagenomic data sets have been suggested previously (Mitra et al., 2009; Liu et al., 2011; Su et al., 2012; Jiang et al., 2012), based on quantifying abundances over a relatively small number of predetermined features requiring existing annotation. Up to some thousands of known taxa, genes or metabolic pathways have been used. We introduce similarity measures that are based solely on raw sequencing reads, and hence, unbiased and insensitive to the quality of the existing annotation. A similar measure has been
previously suggested by Maillet et al. (2012), but only for pairwise comparisons using a method that is computationally too expensive to scale to even modestly large data sets. Furthermore, instead of considering all sequences of particular length, also known as $k$-mers, as has been done earlier for other tasks and by Maillet et al. (2012), we employ an efficient distributed string mining algorithm to find informative subsequences that can be of any length.

In order to deal with the very large number of features some feature selection is necessary. Previous approaches for detecting relevant features in metagenomic data have been based on direct comparison of two classes of samples. Again, most of these methods work on up to some thousands of features (White et al., 2009; Parks and Beiko, 2010; Segata et al., 2011), with the notable exception of one study (Qin et al., 2012) where quantification and association testing was done for over 4.3 million predefined genes. Without feature selection one can use short $k$-mers (Baran and Halperin, 2012) or limit to a set of $k$-mers that are likely to be informative, such as $k$-mers associated with well characterised protein families (Edwards et al., 2012). While there are no previous examples of unsupervised feature selection for metagenomics, it is a common practice in information retrieval with text documents (Yang and Pedersen, 1997); a particularly relevant method assesses the entropy of the distribution of documents in which a specific term occurs (Largeron et al., 2011).

We evaluate the performance of the proposed unsupervised, unconstrained retrieval method on synthetic data, as well as metagenomic samples from human body sites (Qin et al., 2010, 2012; The Human Microbiome Project Consortium, 2012). To evaluate the performance of the retrieval engine, we use external validation based on a ground truth similarity between two samples. To simplify this process, we consider a binary similarity, which is crude but easily accessible. The human gut samples in (Qin et al., 2010, 2012) come from studies exploring the change in bacterial species composition between healthy persons and either inflammatory bowel disease or type II diabetes. We utilize disease state to construct a binary ground truth. Thus, we study if, given the metagenomic sample of a person with a disease, the retrieval finds metagenomic samples related by having the same disease. In the body site data (The Human Microbiome Project Consortium, 2012) we use the body sites as ground truth to investigate whether it is possible to identify the bacterial communities at different body sites in an unsupervised setting without the need of reference genomes. It should be noted that especially for the gut data, two samples may be related in other ways too. The external validation with one simple ground truth nonetheless provides an objective platform for comparing different methods. Given that the method is unsupervised and hence completely oblivious of the disease labels, if such retrieval is successful it is a promising starting point for developing methods for leveraging data from earlier patients in early detection of disease and personalized medicine.

2 APPROACH

Our objective is to extract and select suitable features for representing WMS sequencing samples and to form a pairwise dissimilarity measure for a collection of such samples. Given this dissimilarity one can query with a sample and retrieve other samples that are similar to it (Fig. 1). The measure needs to be reasonably rapidly computable, yet captures relevant differences between the samples, and does all this with as little prior biological knowledge and annotations as possible, since detailed quantitative prior knowledge is typically not yet available for metagenomics.

Evaluating dissimilarity requires representing the metagenomic sample in a suitable feature space. A standard choice for representing objects over strings is to estimate the $k$-mer frequency values, where a $k$-mer here is a string of $k$ letters from the DNA alphabet \{A,C,T,G\}. Therefore, there are $4^k$ possible $k$-mers for any given $k$. It is standard practice to set $k$ to a specific value, typically a small value to keep the estimation problem tractable both computationally and statistically. A larger $k$ would give better discriminability but not without bounds, as for finite data set sizes there simply is not enough data to estimate long $k$-mers. We argue that instead of setting $k$ to a particular value, it is more effective to estimate all possible $k$-mers for all possible $k$ which the data supports. This makes the problem more challenging, since the number of such observed different $k$-mers for large $k$ becomes very large and they become more susceptible to sequencing errors. Focusing on $k$-mers appearing more than once in a sample helps significantly because it is relatively rare to have the exactly same sequencing errors in two independent reads.
we normalize the frequency $f(s, w)$ by a sample-specific constant $\sigma(s)$, which is proportional to the total number of base pairs in a sample, and $\sigma(s) = 1$ for the largest sample in the collection in terms of total base pair count, obtaining

$$f(s, w) = \frac{f(s, w)}{\sigma(s)}.$$  

(1)

The $\sigma(s)$ can be interpreted probabilistically as the probability of observing a sequence in the actual sample, assuming every sample had the same number of base pairs to start with but some have been lost in the processing.

In order to estimate the relative frequencies, we place a conjugate symmetric Dirichlet prior on the parameters of the multinomial distribution over the observed counts. The common choice of uniform prior distribution corresponds to a Dirichlet distribution with all parameters equal to 1. This yields a posterior mean estimate of the relative frequency values as

$$p(s|w) = \frac{f(s, w) + 1}{\sum_{s' \subseteq S} [f(s', w) + 1]}.$$  

(2)

The Dirichlet prior with all parameters equal to one is ubiquitous in document retrieval. It is particularly suitable for metagenomics due to the following observations: First, the distributed string mining algorithm (described below) trades off low k-mer counts for speed and ignores any k-mers that are present only once in a sample. The pseudo-count from the prior makes up for this missing count. Second, adding pseudo-counts assists in playing down the significance of very rare k-mers that may appear due to sequencing errors in the filtering step without affecting other k-mers too much.

Finally, given the massive number of potential k-mers, it is crucially important to improve signal-to-noise ratio by focusing on the informative ones. For the unsupervised tasks of comparing the samples, obviously only k-mers which distinguish between the samples are informative. As a concrete example, consider a k-mer that is present in all samples with a similar abundance. It certainly does not give information useful for comparing samples. In the other extreme, if a k-mer is present in one specific sample, but not in any other, it is potentially a spurious k-mer due to sequencing error, and in any case does not help in comparing samples either. On the other hand, if a k-mer is present in some samples, but not all, then it gives information that those samples are similar in a specific sense. Informativeness in this sense can be measured by the entropy $H$ of the distribution of the k-mer over the samples: we filter the k-mers based on the conditional entropies

$$H(S|w) = -\frac{1}{\log(|S|)} \sum_{s \in S} p(s|w) \log p(s|w);$$  

(3)

a k-mer is taken into account in distance computation only if the normalized entropy is lower than a certain threshold $e$. By design $0 \leq H \leq 1$. Notice that in standard information theory terminology higher entropy implies higher information. However, in our context an informative k-mer has low entropy. Also, due to the Bayesian estimation, a spurious k-mer having only very small counts will have large conditional entropy and will be filtered out.

The optimal value of threshold $e$ varies with datasets. It can be ‘optimized’ in a supervised manner by utilizing a training set where we have labelled samples. In the absence of a labelled set, we suggest taking the ‘average’ of distance metrics computed over the potential thresholds as the final metric. We refer to the final metrics in the two cases as optimized metrics and average metric. In our experimental set-up, we randomly make a 50-50 split of a given dataset in training $S_{tr}$ and testing $S_{te}$ sets: $S_{tr} \cap S_{te} = \emptyset$, and $S_{tr} \cup S_{te} = S$. We use $S_{tr}$ to optimize the entropy threshold: we query with samples in $S_{tr}$, and retrieve relevant samples within the same set to observe which entropy threshold results in the best retrieval result (see Sec. 3.4 for details). While comparing the performance of two methods we always present the evaluation over $S_{tr}$, we query with samples within $S_{te}$, and we retrieve relevant samples from $S$ (not just $S_{tr}$). Notice that the training set can also be used to judge the importance of individual features.

To make the method computationally efficient we treat each k-mer as an independent feature. We compute a Bayesian estimate of their relative frequencies across samples. The employed prior helps in suppressing noise caused by small observed read counts. In the filtering step the abundance distribution of each k-mer over samples is used to judge informativeness of the k-mer for retrieval; a k-mer with constant abundance does not have discriminative power and, in the other extreme, a k-mer which is present in only one sample cannot generalize over samples. We show that the filtering step significantly improves the retrieval performance with most datasets and distance measures. Finally, we compute the dissimilarity between two samples across the features as a weighted average of distances between relative frequencies of individual k-mers. Treating each k-mer as an independent feature allows us to execute these steps fast without explicitly storing the intermediate results. Such simplified distance measures are necessary to guarantee scalability given the extremely high dimensionality of the k-mer features.

To summarize, we introduce methods to i. estimate the frequencies of a large number of k-mers over multiple samples, ii. decide if a k-mer is informative or uninformative in the context of a retrieval task, iii. compute a distance metric using the filtered k-mer frequencies, and iv. execute these steps fast without explicitly storing the frequency values. Fig. 2 summarizes the method.

3 METHODS

3.1 Estimating k-mer frequencies: normalization, filtering

In order to perform the feature selection or filtering, we first compute Bayesian estimates of the relative frequencies $p(s|w)$ of each k-mer $w$ over samples $s \in S$ using observed frequencies $f(s, w)$ of the k-mers. These are distributions over samples for each k-mer that are computed independently for each k-mer for reasons of computational efficiency.

Even if the relative abundance of a k-mer is the same in every sample, the observed frequencies may differ because of different sequencing depth or coverage in different samples. To tackle this issue we employ normalization:
3.2 Algorithms to extract informative k-mers

Our main computational challenge is to extract all informative k-mers from large-scale datasets in feasible time and space. Recall that the filtering step relies on knowledge over multiple samples to decide if the respective k-mer is informative for the retrieval task or not. Since the typical collections of WMS samples are huge in size, we cannot assume that even the plain input fits into the main memory of any single machine. To process these large-scale datasets, the computation needs to be done either using external memory (i.e. disk) or in a distributed manner (i.e. a computer cluster). We review two approaches: k-mer counting (Marais and Kingsford, 2011; Rizk et al., 2013) and distributed string mining (Valimäki and Puglisi, 2012). The first one is a standard approach in the literature for fixed k, but has several limitations when applied in our context of multiple samples and large-scale data. We show that the latter approach is more flexible in this context and can also be generalized to extract informative k-mers over all values of k simultaneously.

Jellyfish (Marais and Kingsford, 2011) and DSK (Rizk et al., 2013) are examples of recent algorithmic improvements in k-mer counting. Both tools use hash tables to compute the k-mer distribution for a given (fixed) k. In both tools, space-efficiency is achieved by keeping most of the hash table on disk. The main drawback with these disk-based approaches is that they are aimed at counting k-mers in a single sample and extending them over to multiple samples is non-trivial. For example, Jellyfish could, in principle, be extended to count k-mers over multiple samples: the authors give a roughly linear time algorithm to merge two or more hash tables. However, the intermediate k-mer counts would need to be stored on disk, which requires significant amount of additional space, and the merge-phase is not parallelized (Marais and Kingsford, 2011, User manual, Sect. Bugs).

The decision whether a particular k-mer is informative or not is made by looking at its frequency over all the given WMS samples. We tackle this problem by a Distributed String Mining (DSM) framework (Valimäki and Puglisi, 2012) that can handle multi-sample inputs by utilizing a computer cluster. The main advantages of this framework are that (i) load-balancing divides the data and computation over multiple cluster nodes, (ii) intermediate k-mer counts are not stored explicitly, and (iii) there is no additional disk I/O strain, except reading through the input once. These advantages allow terabyte-scale data analysis on a cluster having no additional disk I/O strain, except reading through the input once. It allows us to extract the informative k-mers either for a fixed k or over all values of k in feasible time.

The DSM framework is based on a client-server model. The clients have one-to-one correspondence to the given samples, each client being responsible for computing the frequencies within the designated sample. The client-side computation relies heavily on suffix sorting techniques and on space-efficient data structures for strings (Valimäki and Puglisi, 2012): the input data are first preprocessed into a compressed representation, which replaces the input data and acts as an efficient search structure. The server-side computation is more straightforward: the server simply merges the (sorted) input from the clients, computes the entropies and updates the distance matrices. Fig. 3 gives a toy example of the client-server interaction. Two crucial observations are needed to keep the whole computation and transmission costs feasible. First, the informative k-mers can be seen as a subset of left-right-branching substrings, i.e. substrings whose instances have differentiating continuation on both left and right. More formally: substring w of string T[1, n] is called right-branching if there exists two symbols α and β such that α ≠ β and both wα and wβ are substrings of T. Similarly, a substring w is left-branching if aw and bw, α ≠ β, are substrings of T. If a substring is both left-branching and right-branching we say it is left-right-branching. Second, for any string of length n, there are at most O(n) left-right-branching substrings, and the total length of all such substrings is bounded by O(n log n) (Kärkkäinen et al., 2009, Theorem 1).

The first observation allows us to reduce the client-side computation to a smaller set of substrings: it is easy to see that if k-mer w, having frequency f’(s, w) ≥ 2, is non-branching, then there exists a substring w’ of length k’ > k that is left-right-branching and has exactly the same frequency, i.e., f’(s, w) = f’(s, w’). It follows that the frequency of non-branching k-mers can be deduced from the branching k’-mers, and the left-right-branching substrings contain all the necessary information for us to detect informative k-mers. The second observation guarantees a feasible transmission cost between clients and servers: the upper bound for the concatenation of all left-right-branching substrings also acts as an upper bound for both the server-side running time and the amount of communication needed. The drawback of restricting to left-right-branching substrings is that the informative k-mers that we are able to detect have to appear at least twice in a sample, although this limit may be useful in pruning spurious k-mers introduced by sequencing errors. More detailed explanation and analysis of the DSM framework is given in (Valimäki and Puglisi, 2012). A software implementation of the DSM framework is available at https://github.com/HITMetagenomics/dsm-framework.

3.3 Dissimilarity metrics

Having extracted the informative k-mers, we use them to compute the dissimilarity between two metagenomic samples. We consider three dissimilarity metrics that can be computed easily over a large number of k-mers in sequential manner. i.e. one k-mer at a time, and without storing all the k-mer frequencies explicitly. To utilize the natural variance structure of the k-mers—some are more abundant than others—we weight the relative frequencies of each k-mer by their respective total counts, i.e., we utilize the absolute frequencies f(s, w) as defined in (1).

We mainly use the very simple Jaccard distance which does not consider abundances at all, only whether a k-mer occurs or not. Given two sets s1 and s2 of k-mers detected as present in two different samples, Jaccard distance measures how many elements are shared between these two sets. Mathematically, it is defined as

\[ D_{\text{count}}(s_1, s_2) = 1 - \frac{|s_1 \cap s_2|}{|s_1 \cup s_2|}. \]

Despite its simplicity, we observe that Jaccard distance performs well; a potential reason is its robustness to measurement noise and effectiveness when two metagenomic samples differ in terms of presence and absence of certain species or functionalities. We assume a k-mer is present in a sample if its frequency is more than 2.

We also experiment with two metrics that use the abundance information:

I. Variance-stabilized Euclidean distance: An obvious distance measure between two metagenomic samples s1 and s2 is the Euclidean distance between their respective k-mer frequencies. We consider the distance metric

\[ D_{\text{sqrt}}(s_1, s_2) = \sum_w (\sqrt{f(w, s_1)} - \sqrt{f(w, s_2)})^2 \]

which can be computed sequentially as new informative k-mers are extracted. The square root transformation is the variance stabilizing transformation for Poisson distribution—a popular model for quantitative sequencing data.

II. Log transformed Euclidean distance: We also consider the same metric but with log transformation which is a popular approach in document retrieval, i.e.,

\[ D_{\log}(s_1, s_2) = \sum_w (\log(1 + f(w, s_1)) - \log(1 + f(w, s_2)))^2. \]

The motivation for using the log transformation is that it decreases sensitivity to high frequency counts: some k-mers are present in high abundance in almost every genome, for instance k-mers from the marker gene, and the log transformation reduces their effect in the metric.

3.4 Evaluation metric

We evaluate the performance of the dissimilarity metric in terms of its performance in the task of retrieving relevant samples given a query...
Exploration and retrieval of whole-metagenome sequencing samples

Table 1. Computational resources required by the distributed string mining on different datasets. We report wall-clock times and total CPU times for both fixed \( k = 21 \) and over all \( k \); Preprocessing is done only once, separately from the actual computation. Total memory is the memory requirement over all computation nodes. Experiments were ran on a cluster of Dell PowerEdge M610 nodes having 32 GB of RAM and 16 cores. Simulated data and MetaHIT were run using up to 8 nodes. T2D-P2 was run using 32 nodes allowing more parallelization at the server-side. HMP was ran on a cluster of 20 nodes with 2x10-core Xeon CPUs and 256 GB RAM.

Table 1 gives an overview of the computational resources required for both classes and for the other half of the species the parameters were randomly permuted. For example, given 5 species the assigned parameters could be: (0.3, 0.2, 0.6, 0.1, 0.9) and (0.9, 0.2, 0.3, 0.1, 0.6) where the parameters for the second and fourth species are the same, but for the other species they were permuted. The exact species and corresponding parameter values can be downloaded from https://github.com/HITMetagenomics. The resulting datasets are: HIGH-C, relatively easy data with high coverage (10×6 reads/sample); LOW-C, relatively difficult data with low coverage (2×6 reads/sample); MIXED-C, mixed data with half the samples from HIGH-C and the rest from LOW-C to simulate varying sequencing depth; and HIGH-V AR, relatively difficult data with same coverage as HIGH but additional noise in the class distributions to simulate more overlap between classes. To elaborate, the relative abundance of species is \( \text{phigh-var} = 0.5 \text{phigh} + 0.5 \text{noise} \) where noise is generated from a symmetric Dirichlet distribution with all parameters equal to 1.

4 RESULTS

We evaluated the retrieval performance on three human metagenomics datasets:

1. MetaHIT (Qin et al., 2010), 124 metagenomic samples from 99 healthy people and 25 patients with inflammatory bowel disease (IBD) syndrome. Each sample has on average 65 ± 21 million reads. Our goal was to retrieve IBD positive patients.

2. T2D Phase II (Qin et al., 2012), 199 metagenomic samples from 100 healthy people and 99 patients with type II diabetes. Each sample has on average 47 ± 11 million reads. Our goal was to retrieve diabetic patients. We chose to explore the phase II data instead of the phase I data since the former has higher coverage; about 40% more reads than the latter.

3. HMP (The Human Microbiome Project Consortium, 2012), 435 metagenomic samples from 10 different body sites (see Table 1 in the supplement). Out of 690 samples that passed the QC assessment (http://www.hmpdacc.org/HMASM/), we discarded 255 samples that had less than 1% of the number of reads of the largest sample.

To recapitulate, for MetaHIT and T2D-P2, our goal is to observe if given a positive sample, e.g., from a patient with a particular disease, one can retrieve relevant samples, i.e., with similar disease; whereas for HMP, our goal is to observe if given a sample from a particular body site, one can retrieve relevant samples, i.e., samples from the same body site. For all data we applied a quality threshold of 30 and ignored any base pairs with quality less than the threshold. Table 1 gives an overview of the computational resources required for each data set. Additionally, number of \( k \)-mers used by different methods for each data set is available in the supplement, Fig. 1.

Retrieval of samples with similar annotation: We applied the proposed approach and a number of alternatives to retrieval of similar samples from the same data set and evaluated by how many
of the retrieved samples had the same annotation: class label, disease state or body site. A comparison of the obtained mean average precision values averaged over queries by all positive samples is shown in Fig. 4. The results show the performance achieved by the ‘optimized metric’. The alternatives we considered were: i. retrieval performance based on the proposed distances between frequencies of 21-mers appearing in known protein families (FIGfams) with added pseudo-counts but without entropy filtering (Meyer et al., 2009); ii. retrieval based on Bray-Curtis dissimilarity between relative species abundances estimated using MetaPhlAn (Segata et al., 2012) (each feature is a species found in at least one sample; no regularization added); and iii. retrieval based on $d_3^3/|M_2|$ distances between relative frequencies of 3-mers (Jiang et al., 2012).

For the simulated data, the two classes differ only by the relative species abundance; thus, retrieval based on ground truth abundance can be considered to give an upper limit for the performance. For HIGH-C and HIGH-VAR, the proposed method performs closer to the ground truth performance than any other methods, although the difference from ground truth performance is still statistically significant. For LOW-C, the performance of all methods, except the protein family based comparison, drop compared to HIGH-C, while for MIXED-C the performance is again close to HIGH-C despite the presence of low coverage samples. This is an encouraging observation showing the robustness of the proposed approach to varying sequencing depths.

For the real data sets the proposed approach yielded statistically significantly higher mean average precision than any of the alternatives ($p < 0.05$) for all the datasets, except T2D-P2 where protein family based comparison works equally well. Interestingly, the abundance-based retrieval performs relatively poorly here, suggesting that the differences between the classes cannot be easily captured by species composition alone, while the proposed $k$-mer features can provide a better separation. Retrieval based on the known protein family performed fairly well, but slightly worse than the proposed approach on MetaHIT. We observe that for MetaHIT, Jaccard metric performs poorly; however, a change of metric to log significantly improves the performance for all methods. Otherwise, all metrics usually work equally well over different data sets.

**Effect of using specific or unspecific $k$-mer length:** We next compared the proposed approach of using all $k$-mers to using a specific $k$. The retrieval performance using ‘optimized metric’ is shown in Fig. 5 (and Fig. 2 in the supplement). The figures show the complete distribution of average precision values over different queries whose mean is the mean average precision of Fig. 4. The performance of the proposed method is usually better than with any individual $k$. Thus, the proposed method appears to be a relatively safe choice that does not suffer from catastrophically bad performance on any of the data sets.

**Effect of the entropy filtering:** Next, we evaluated the efficacy of filtering the informative $k$-mers against retrieval performance
without the filtering operation. The results are presented in Fig. 6 (and Fig. 3 in the supplement). We observed that entropy filtering usually improved retrieval performance for all tested $k$-mer lengths when using the ‘optimized metric’, although the improvement might not always be statistically significant. Although ‘average metric’ often provides significant performance, it might not always improve over performance without filtering. Also, retrieval performance of FIGfam may or may not improve with entropy filtering (‘optimized metric’ and ‘average metric’ selected in the same way as other methods).

Comparison across different metrics: Finally, we evaluated the retrieval performance over different dissimilarity metrics. We presented the performance using ‘optimized metric’ for different metrics in Fig. 7 (and Fig. 4 in the supplement). We observed that the simple presence-absence-based metric $D_{\text{count}}$ performed at least as well as abundance-sensitive log and sqrt metrics, except for the MetaHIT data for which the other metrics performed the better.

5 CONCLUSION

In the wake of collecting multiple samples from similar environments information retrieval for metagenomic samples is expected to become a handy tool in metagenomics research. In this paper, we have addressed the problem of retrieving relevant metagenomic samples given a query sample from the same collection. The novelty of the proposed approach is that it is unsupervised, and does not rely on the availability of reference databases. We have suggested employing $k$-mer frequencies as feature representation; however, rather than exploring $k$-mers of a fixed $k$, we have scanned through all possible $k$-mers of all possible $k$’s using distributed string mining, and have proposed appropriate filtering technique to discard uninformative $k$-mers. Being reference-free, our method is capable of focusing on novel sequence markers, such as ones identifying novel bacterial strains. On the other hand, sensitivity especially on low-coverage species may be lower than using reference-based approaches. Like most read-counting-based approaches, our method can be sensitive to technical variation and changing biases in the sequencing process. For most reliable results, the data set should be measured as uniformly as possible. The distributed algorithm relies on dedicated cluster hardware having sufficient total amount of main memory. The development of an efficient secondary-memory-based algorithm is an important topic of future work. The overall computational requirements scale in near-linear manner (Välimäki and Puglisi, 2012). We have evaluated our method on both real and simulated data, and observed that the approach can effectively retrieve relevant metagenomic samples, outperforming both the FIGfam method based on known highly informative protein families as well as retrieval based on species composition of the samples.

ACKNOWLEDGEMENT

The authors would like to thank Ahmed Sobih for his help with the MetaPhlAn experiments on MetaHIT and T2D-P2. Part of the calculations presented above were performed using computer resources within the Aalto University School of Science “ScienceIT” project.

Funding: This work was supported by the Academy of Finland (project numbers 140057, 250345, 251170 and 259440).

REFERENCES

Fig. 6. Comparison of the best retrieval performance achieved with ‘optimized metric’ (middle), ‘average metric’ (right) and without entropy filtering (left), for proposed approach ‘All’, individual k’s as well as FIGfam based distance metric. The metrics are ‘optimized’/‘averaged’ over 101 equally spaced threshold values between 0 and 1. Each errorbar line shows the MAP value along with the standard error. The grey horizontal line shows retrieval by chance: MAP computed over zero dissimilarity metric. An arrow (if present) over a method implies whether the performance of the corresponding method (top: ‘average metric’, bottom: ‘optimized metric’) is better (↑) or worse (↓) than when entropy filtering is employed: The stars denote significance level: 0 < *** < 0.001 < ** < 0.01 < * < 0.05. We observe that filtering has a positive impact on the retrieval performance.

Fig. 7. Comparison of the best retrieval performance for different distance metrics using all k-mers. They show a violin plot of the average performance over queries by all positive samples in the data sets. The ‘optimized metrics’ have been selected over 101 equally spaced threshold values between 0 and 1: the box denotes the MAP value. The horizontal lines show retrieval by chance: AveP computed over zero dissimilarity metric. Straight line is the mean, and dotted lines are 5%, and 95% quantiles respectively, when number of relevant samples differ for different queries. An arrow (if present) over a method implies whether the corresponding method performs significantly better (↑) or worse (↓) than the other methods (denoted by their colors): The stars denote significance level: 0 < *** < 0.001 < ** < 0.01 < * < 0.05. We observe that different distance metrics usually demonstrate similar performance.
